ABSTRACT

Laboratory spectra through the mid-infrared (4000 to 500 cm⁻¹ [2.5–20 μm]) have been used to calculate the optical constants (*n* and *k*) and integrated absorption coefficients (*A*) for a variety of pure and mixed molecular ices of relevance to astrophysics. The ices studied were H₂O, CH₃OH, CO₂, OCS, CH₄, CO₂ + CH₄, CO₂ + OCS, CO + CH₄, CO + OCS, O₂ + CH₄, O₂ + OCS, N₂ + CH₄, N₂ + OCS, H₂O + CH₄, H₂O + OCS, and H₂O + CH₃OH + CO + NH₃. In addition, the measurements have been extended through the far-infrared (500 to 50 cm⁻¹ [20–200 μm]) for the H₂O, CH₃OH, and H₂O + CH₃OH + CO + NH₃ ices.

Subject headings: line: identification — molecular data

1. INTRODUCTION

Accurate optical constants are extremely useful in any field of scientific research where radiative transfer through solid materials is of importance. Much of our understanding of the universe is determined by the interaction of light with solid matter. Apart from the fundamental insight these constants provide into the interaction of light with matter on a microscopic scale, the real (*n*) and imaginary (*k*) indices of refraction of materials, as well as individual band strengths, can be of great practical importance. While the optical constants of gases, liquids, and room temperature solids have been the subject of many studies, those of ices have not, because of the difficulties inherent in making these measurements. Yet the optical properties of ices can be very important for astrophysical applications. For example, ices play a large role in determining global weather patterns by controlling the amount of radiant energy striking the Earth's surface versus that dissipated among the icy particles in the atmosphere. Similar important roles are played by the interaction of light with icy aerosols and surfaces on other objects in the solar system (Klinger et al. 1985; Cruikshank & Brown 1993). For example: (i) the Martian polar caps are thought to be H₂O- and CO₂-rich ices (Pollack & Toon 1982); (ii) most of the satellites of Jupiter and Saturn contain H₂O-rich ices, except for Io, which is dominated by frozen SO₂ (Burns & Matthews 1986); (iii) Neptune's satellite Triton shows evidence for N₂-, CO-, CH₄-, and perhaps CO₂-containing ices (Burns & Matthews 1986); (iv) the ices in the Pluto/Chiron system appear to contain H₂O and CH₄ (Cruikshank & Brown 1993); and (v) comets are known to be mixtures of molecular ices and minerals (Wilkening 1982). Farther from home, small (<0.3 μm) icy interstellar grains regulate radiative energy transfer within interstellar clouds and hence determine their energy balance and spectra. In this way, these grains influence such fundamental processes as star formation and cloud evolution (Hollenbach & Thronson 1987). Among the molecules identified in such

icy grain mantles are H₂O, CH₃OH, CO (Tielens 1989), CH₄ (Lacy et al. 1991), and possibly OCS (Geballe et al. 1985). Our solar system is thought to have formed from such a dense cloud, and it is generally believed that interstellar icy grains are the building blocks of comets (Burns & Matthews 1986).

The interpretation of the data from all of these very different environments and understanding of their significance to processes as wide-ranging as determining the Earth's climate, the history of the solar system, or the chemistry of the interstellar medium require that one know how these ices interact with light. Airborne, as well as Earth-based and orbiting, observatories take data which require this information for analysis. For example, the infrared spectra of many of these objects are produced by a superposition of effects due to absorptions and reflections from ices and their surfaces. Interpretation of the spectra require the application of fully developed models such as those associated with Hapke theory (Hapke 1981) and Mie theory (van de Hulst 1981; Bohren & Huffman 1983), which, in turn, requires a knowledge of the *n* and *k* values appropriate for the ices being studied.

The infrared spectra of atmospheric aerosols as well as microscopic grains of interstellar dust in dense molecular clouds are dominated by ice absorption features. A quantitative interpretation of these data requires detailed comparison with laboratory data. Unfortunately, the direct comparison of spectra is hampered by the fact that the experimental studies are necessarily done on thin films, while the measurements are associated with small particles (<0.3 μm in the case of interstellar dust grains). The interaction of light with small particles can be quite different from that with bulk films, resulting in differences between the profiles of absorption features between the laboratory spectra and the interstellar spectra. Several major effects are often seen (Hapke 1981; van de Hulst 1981). First, when the particle size, *a*, is comparable to the wavelength, λ (i.e., $a \approx \lambda/2\pi$), scattering effects become important. In general, this can lead to the presence of a scattering wing on the long-wavelength side of a band which could mistakenly be at-

tributed to additional absorption. Second, in the neighborhood of a strong transition, surface modes can completely dominate the spectral profile. These surface modes can lead to appreciable frequency shifts and intensity enhancements of an absorption feature. Moreover, they may lead to the presence of multiple peaks in a small-particle spectrum where the bulk film shows only a single feature. An example of these effects in interstellar CO-containing ices can be found in Tielens et al. (1991).

Theoretical calculations of these small-particle effects require knowledge of the real and imaginary parts of the index of refraction. A few laboratory studies of astrophysically relevant ice mixtures have been reported in the literature (Hagen, Tielens, & Greenberg 1981, 1983; Leger et al. 1983; d'Hendecourt & Allamandola 1986; Sandford et al. 1988; Tielens et al. 1991; Sandford & Allamandola 1991). Generally, these studies present only the integrated strength of absorption features. In a few cases, the index of refraction was determined, often only at a single temperature or over a limited spectral range.

Here we report the complete index of refraction (n and k) of a large number of ices over a wide range of temperatures. These ices include pure materials as well as mixtures that are relevant to interstellar, planetary, and terrestrial environments. The ice samples and their concentrations were chosen to reflect those species and their relative abundances that are known or expected to be found in the solar system and/or the interstellar medium. The pure icy materials studied were H₂O, CH₃OH, CH₄, CO₂, and OCS. The binary mixtures studied were H₂O:CH₄ = 20:1, CO:CH₄ = 20:1, CO₂:CH₄ = 20:1, N₂:CH₄ = 20:1, O₂:CH₄ = 20:1, H₂O:OCS = 2:1, H₂O:OCS = 20:1, CO:OCS = 20:1, CO₂:OCS = 20:1, N₂:OCS = 20:1, and O₂:OCS = 20:1. Finally, the ices H₂O:CH₃OH:CO:NH₃ = 100:50:1:1 and H₂O:CH₃OH:CO:NH₃ = 100:10:1:1 (hereafter referred to as the strong and weak interstellar mixes, respectively) were chosen to reproduce the ices in interstellar clouds and to bracket the solid state methanol abundances reported for the interstellar medium (Tielens & Allamandola 1987; Grim et al. 1991; Allamandola et al. 1992).

This paper is organized as follows. The experimental procedures are presented in some detail in § 2. In § 3 the method used to calculate the values of n and k is described. The technique used to deduce the integrated absorbance values (A) of observed absorption features is described in § 4. In § 5 particulars about each individual ice are given. Last, the tables of A values and the calculated n and k values are presented.

2. EXPERIMENTAL PROCEDURES

2.1. General Description

The apparatus used to prepare and study the ice samples in these experiments was slightly modified from that previously used for interstellar and cometary ice analogs (Allamandola, Sandford, & Valero 1988). A schematic of the sample chamber is shown in Figure 1. An infrared transmitting substrate is suspended on an infrared window inside a high-vacuum chamber and cooled by a closed-cycle helium refrigerator. The vacuum chamber is equipped with multiple inlet ports, and the cooler is mounted in such a way that the infrared window can be rotated to face any of these ports without breaking the vacuum. In a typical experiment, the window is

a. Sample Deposition Configuration

b. Spectrum Collection Configuration

FIG. 1.—Schematic of the vacuum chamber and sample holder used in these studies. The two pictures show the system in the configurations used (a) during sample deposition and (b) during infrared spectral measurement.

cooled to 10 K and rotated to face the beam of an infrared spectrometer. A “background” spectrum is then taken of the blank window, after which the cold window is rotated to face the sample inlet port. Ice samples are made by depositing a suitable gas mixture through this port and onto the cold substrate. The ice sample is again rotated to face the beam axis of an infrared spectrometer, and a transmission spectrum is recorded. The sample is subsequently warmed in a stepwise fashion to the sublimation temperature of the ices’ main constituent. At each step, the ice is allowed to thermally equilibrate at least 10 minutes before an additional infrared spectrum is recorded. Specific aspects of this generalized procedure are considered in more detail in subsequent sections.

2.2. Gas Sample Preparation

All the individual sample components used for these experiments either were gaseous or possess a significant vapor pressure at room temperature. Gas mixtures were prepared by combining the constituent compounds in their desired molar ratio in a volume-calibrated, greaseless, glass vacuum manifold and glass sample bulb. The system is evacuated through an oil diffusion pump (Edwards Diffstack Series 63M) backed by a rotary mechanical pump (Edwards E2M2). Backstreaming of pump oil into the sample system is prevented by a liquid nitrogen cold trap located between the manifold and the

pumps. The pressure in the system can be monitored over a wide range by an ion gauge, a thermocouple gauge, two diaphragm manometers (0–1 bar and 0–0.1 bar), and a silicone oil manometer. The manifold is wrapped with heating tape to facilitate bakeouts (under vacuum) to clean the system between samples. The sample preparation system routinely operated in the 10^{-5} mbar range. Since the partial pressures of mixture components typically fell in the 1–100 mbar range, sample contamination from the vacuum system was limited to one part in 10^5 – 10^7 . The compounds used and their purities were as follows: CH_3OH (liquid), Fisher Photrex grade, 99.98% purity; CH_4 (gas), Matheson U.H.P., 99.97% purity; CO (gas), Matheson C.P., 99.5% purity; CO_2 (gas), Matheson Bone Dry, 99.8% purity; H_2O (liquid), triply distilled; NH_3 (gas), Matheson Anhydrous, 99.99% purity; N_2 (gas), Airco Dry, 99.9% purity; OCS (gas), Matheson, 97.5% purity; O_2 (gas), Matheson Extra Dry, 99.6% purity.

2.3. The Sample Chamber

The ice samples were prepared and their spectra measured in a stainless-steel vacuum system. This system consists of a large manifold with Viton O-ring seals evacuated by an oil diffusion pump (Edwards Diffstack Series 100M) backed by a mechanical pump (Edwards E2M5). A liquid nitrogen trap between the mechanical and diffusion pumps prevents the mechanical pump oil from contaminating the system. Ion and thermocouple gauges attached to the manifold allow continuous monitoring of the internal pressure. At room temperature, the system typically operated at a pressure of 1×10^{-7} mbar. With the sample finger and its protective cold shield cooled to 10 K, the system pressure was near 2×10^{-8} mbar above the diffusion pump. The pressure at the sample was considerably lower.

The sample finger resides at the end of a manifold in a vacuum head which contains four major ports, situated at 90° with respect to one another, that can be utilized for a variety of applications. The substrate, an infrared transmitting window, is suspended from a cold finger in the center of the vacuum head and can be rotated through a full 360° to face any of the ports without breaking vacuum. Vacuum windows, mounted over opposing ports, allow the infrared spectrum of the sample to be measured. The substrate and vacuum windows used for these experiments depended on the application. A CsI substrate and KBr vacuum windows were used in the mid-infrared, while polyethylene was employed throughout for the far-infrared region. The temperature of the substrate is controlled by a water-cooled, closed-cycle helium refrigerator (Air Products Displex CSW 202). The minimum substrate temperature attainable with this system was 9–10 K for CsI windows and 16–18 K for polyethylene windows. A small resistive heater, mounted on the cold finger just above the substrate and operated by a programmable controller, allows the substrate temperature to be maintained or changed in a controlled fashion from the low-temperature limit to room temperature. The temperature of the substrate is monitored with an absolute accuracy of ± 1 K using an Fe-Au/chromel thermocouple pressed into the indium gasket between the window and its holder. The temperature of the coldest part of the cryostat is also monitored using an identical thermocouple. This is calibrated against the vapor pressure of hydrogen in a closed capillary tube which is also mounted on the cryostat.

2.4. Ice Sample Preparation

Once the gas sample bottle was mounted on the vacuum manifold and the substrate was cooled to 10 K, the cold window was rotated to face the sample inlet port (Fig. 1). A modified microflowmeter tube (Gilmont, tube F3000) was used to regulate the rate at which the sample gas was deposited on the cold substrate. Samples for these experiments were typically deposited at a rate of a few hundredths of a millimole per hour, corresponding to several microns per hour in thickness. Since the diameter of the infrared beam at the substrate is small (≈ 4 mm) compared with the sample size (≈ 1.5 cm), the ice layer can be treated as planar. Typical sample thicknesses in the mid-infrared were 0.5–1.0 μm , while in the far-infrared (where the absorption features are weaker) thicknesses ranged from 5 to 10 μm . The thicknesses of the ice samples were measured by monitoring the temporal variation in the intensity of a HeNe laser beam reflected from the surface of the substrate during deposition. This was accomplished by mounting a photomultiplier tube (Hamamatsu model R955) on the vacuum head such that, with the cold window in its deposition configuration, the intensity of the reflected beam of the spectrometer's internal collimation laser could be monitored (see Fig. 1). The output of the photomultiplier tube was directed to a strip chart recorder (Kipp & Zonen model BD41), so that the interference fringes could be monitored and recorded. The number of interference peaks in the intensity pattern, m , is directly related to the ice's thickness by the equation

$$d = (m\lambda_0)/(2n_{\text{ice}} \cos \theta_{\text{ice}}), \quad (1)$$

where d is the ice thickness (μm), λ_0 is the wavelength of the HeNe laser beam (0.6328 μm), n_{ice} is the visible index of refraction of the ice, and θ_{ice} is the angle of reflection within the ice sample.

2.5. Measurement of Infrared Spectra

The entire sample head of the vacuum system sits in the sample compartment of a Nicolet 740 Fourier transform infrared spectrometer and is positioned so that the infrared beam axis passes unobstructed through the centers of the cold window and two opposing vacuum windows. Once an ice sample was prepared, it was rotated to face the windows through which the infrared beam of the spectrometer passes. The infrared absorption spectra presented here were recorded using two separate optical setups for the mid- and far-infrared. Mid-infrared spectra were obtained by summing 500 scans (interferograms) using a liquid nitrogen-cooled, mercury-cadmium-telluride detector (Nicolet MCT-B) and a KBr beam splitter. The spectral resolution, as defined by the width of an unresolved line, was 0.9 cm^{-1} over the 4000 to 400 cm^{-1} (2.5–25 μm) region. Far-infrared spectra from 675 to 50 cm^{-1} (14.8–200 μm) were recorded using a DTGS detector and Nicolet far-infrared beam splitter. Due to lower detector efficiency and lower energy throughput in the far-infrared, the spectra in this region represent the sum of 1000–2000 scans and were taken at a lower spectral resolution (1.8 cm^{-1}). Spectra in the far-infrared are presented only for those samples which showed appreciable absorption features in this region. The overlap between the mid- and far-infrared spectra (675 to 400 cm^{-1})

allowed corresponding spectra to be reliably knitted together into a single spectrum.

We adhered to a uniform protocol for the collection of spectral data throughout our experiments. First, the substrate was cooled to 10 K (16 K in the far-infrared) and allowed to equilibrate for at least 10 minutes. Since the infrared spectrometer used for these experiments was a single-beam instrument, it was necessary to record a blank background spectrum of 1000 scans (2000 scans in the far-infrared) prior to ice deposition. The number of scans of which the background spectrum was comprised was always chosen to equal or exceed the number of scans in the ice spectrum. Thus, the noise level in the final ratioed spectrum was controlled by the noise in the ice single-beam spectrum. After rotating the head to the deposition position and laying down an ice as outlined in § 2.4, the head was returned to the scan position and the ice spectrum was recorded. The sample spectrum was then ratioed to the background spectrum to yield the single-beam transmission spectrum. The substrate was then warmed at a rate of 2 K minute⁻¹ to the next temperature (the specific temperatures chosen for each ice are given in §§ 5.1–5.18). After achieving the desired temperature, the substrate was allowed to equilibrate for at least 10 minutes before another spectrum was recorded. Because the blank background spectra did not depend on substrate temperature, all the sample spectra were ratioed to the 10 K (16 K) background spectrum recorded at the beginning of each experiment. The procedure of alternate warm-up and spectral measurement was repeated until the temperature at which the primary ice constituent began to sublime was reached. After the experiment, the individual spectra were reviewed, and optical constants were calculated for each temperature at which the spectra showed an appreciable change from the previous temperature step.

3. OPTICAL CONSTANTS

3.1. Calculating the n and k Values

The optical constants were determined using a Kramers-Kronig analysis (Bergmen et al. 1978) of the transmission spectra. Consider a plane-parallel absorbing film of thickness h and complex index of refraction $\mathbf{n} = n + ik$, where n and k are the real and imaginary parts of the index of refraction. The film is situated between two media of refractive index n_0 (vacuum) and n_2 (CsI or polyethylene). For light of normal incidence, the ratio of the transmitted intensity when the film is present to that when the film is absent is given by

$$\frac{I}{I_0} = \left| \frac{e^{ix} t_{01} t_{12} / t_{02}}{1 + r_{01} r_{12} e^{2ix}} \right|^2 = e^{-ah} \left| \frac{t_{01} t_{12} / t_{02}}{1 + r_{01} r_{12} e^{2ix}} \right|^2, \quad (2)$$

where $x = (2\pi/\lambda)hn$, λ is the wavelength in microns, and the Lambert absorption coefficient α is given by

$$\alpha = (4\pi/\lambda)k, \quad (3)$$

The complex reflection and transmission coefficients r_{pq} and t_{pq} of the pq boundary are given by the formulae

$$r_{pq} = (\mathbf{n}_p - \mathbf{n}_q)/(\mathbf{n}_p + \mathbf{n}_q), \quad t_{pq} = 2\mathbf{n}_p/(\mathbf{n}_p + \mathbf{n}_q). \quad (4)$$

Rearranging equation (2), we find for the absorption coefficient

$$\alpha = \frac{1}{h} - \ln \left(\frac{I}{I_0} \right) + \ln \left| \frac{t_{01} t_{12} / t_{02}}{1 + r_{01} r_{12} e^{2ix}} \right|^2. \quad (5)$$

Given the absorption coefficient, we can calculate n from the Kramers-Kronig dispersion relation

$$n(\nu) = 1 + \frac{1}{2\pi^2} \int_0^\infty \frac{\alpha(\nu')}{\nu'^2 - \nu^2} d\nu'. \quad (6)$$

The calculation of n involves, in principle, knowledge of the absorption coefficient over the entire electromagnetic spectrum. However, since electronic and vibrational transitions are well separated in frequency, the former produces only a constant contribution throughout the infrared. Equation (6) can then be written as

$$n(\nu) = n_0 + \frac{1}{2\pi^2} \int \frac{\alpha(\nu')}{\nu'^2 - \nu^2} d\nu', \quad (7)$$

where n_0 is the value of n at the high-frequency end of the infrared, and the integration is now only over the infrared region of the spectrum. For the n_0 values of our samples we have used reported values for the visible refractive index of the sample ice at the D lines of atomic Na ($\lambda = 589$ nm). For ices dominated by CO₂, N₂, O₂, and CH₄ we have used values of $n_0 = 1.22$, 1.22, 1.25, and 1.33, respectively (Hallam & Scrimshaw 1973). A value of $n_0 = 1.33$ was used for our CH₃OH ices. This value was estimated from the value of n_0 for liquid CH₃OH ($n_0 = 1.326$; Weast 1972). A value of $n_0 = 1.24$ was used for ices dominated by OCS. This value was estimated from the value of liquid OCS at -87°C ($n_0 = 1.24$; Grasselli & Ritchey 1975). The value to be used for ices dominated by H₂O is somewhat problematic. Since H₂O ice has many amorphous and crystalline forms, it is not surprising that reported values of n_0 vary (from about 1.26 to 1.35). We have used a value of $n_0 = 1.32$ for H₂O-rich ices. We used $n_0 = 1.30$ for ices dominated by CO, a value consistent with that measured at 1000 cm⁻¹ by Jiang, Person, & Brown (1975).

The computational procedure used to determine the complex refractive index was as follows. Assuming a starting value for \mathbf{n} ($= n_0 = n_{(\text{NaD})}$) at all frequencies, we calculated the absorption coefficient from equation (5) and the imaginary part of the refractive index from equation (3). Using equation (7) we then computed the real part of the refractive index. We then used the resultant n and k values to compute a synthetic spectrum which was, in turn, compared with the real spectrum. This iterative process was repeated, using the new \mathbf{n} values generated in the previous step, until the calculated transmissivity (eq. [2]) differed nowhere from the measured value by more than 0.1%. The number of iterations required to fulfill this requirement depended on the number, strength, and width of the absorption features within the spectrum. It ranged from about 10–20 iterations for the H₂O-dominated ices, which are characterized by broad absorptions, to more than 100 iterations for the CO₂:OCS ice mixture, which had much sharper bands. The correct operation of the program was ini-

tially checked by comparing our results against values already reported in the literature. Since it was necessary to compare against ices having the same composition, temperature, and thermal history, we were restricted to comparisons with values for H₂O (Bertie, Labbe, & Whalley 1969; Hagen et al. 1981; Leger et al. 1983), CO₂ (Wood & Roux 1982; Warren 1986), CO (Roux et al. 1980), and CH₄ (Roux et al. 1980; Pearl et al. 1991). In all cases, good agreement was obtained between the calculated values and those found in the previously published literature.

The absolute accuracy of the calculated optical constants is limited mainly by the accuracy of the measured sample thickness h and of the assumed value of the visible refractive index n_0 of the amorphous ice sample. The measured values of h for our mid-infrared samples are accurate to within 5%. Uncertainty in the adopted values for n_0 is due to the effect of the residual dispersion of the ultraviolet contributions to n_0 between the visible and 4000 cm⁻¹ and the dependence of n_0 on the temperature and crystal structure of the sample. The effect of the above errors would be to impose a global vertical shift on the resultant optical constants. For a given choice of n_0 , however, it is possible to run the iteration process until the synthetic and measured spectra match to within an arbitrarily small amount (0.1% in the case of our studies). Hence, we estimate the maximum *absolute* uncertainty in the calculated optical constants in the mid-infrared to be about 5% (due mainly to the uncertainty in h). Since the far-infrared spectra are scaled to the mid-infrared spectra (see § 5), the absolute error in the far-infrared is expected to be worse. However, the *relative* error between adjacent n and k pairs in both the mid- and far-infrared for a specific data set is closer to 0.1%.

3.2. The Spectral Baseline

Reflections generated at each of the optical interfaces in the system interfere constructively and destructively within the infrared beam as it passes through the vacuum head. Most of these effects cancel out when the sample spectrum is ratioed with the background spectrum, since most of the interfaces in the optical path are present in both spectra. Two interfaces whose effects do not cancel, however, are those between the sample and the sample window and between the sample surface and the vacuum. Interference due to multiple reflections within the sample is manifested as a broad oscillation in the spectral baseline. Depending on sample thickness and index of refraction, this oscillation will pass through anywhere from a fraction of a period to several periods across the spectrum. When the spectrum is used to calculate optical constants, it is necessary to account for this effect in one of two ways.

Since the effect depends on the index of refraction of the sample, it should be possible, in principle, to let the program attempt to fit the entire raw spectrum from first principles. Indeed, these oscillations are implicitly present in equation (2). However, there are several problems with this approach. First, the thickness of the ice layer is known only to within about 5%. This approach also does not account for wavelength-dependent scattering losses from the ice layer during transmission, internal reflections within the cold window, or small errors in positioning the ice layer perpendicular to the infrared beam after deposition. Although all of these effects are

subtle, the resultant period and amplitude of the baseline oscillation in the actual experimental data may differ slightly from that inferred by the program. Hence, the program will interpret these deviations as broad "emission" or "absorption" features in the spectrum. As a result, the program will derive small, nonzero values for k across much of the spectrum to account for these artificial features. Since the computed value for n depends on an integral of k values around the wavelength of interest, such errors will result in a quasi-systematic error in the computed n values. Hence, it is generally not practical to use the program to compensate for all the factors associated with the baseline deviation.

A second, more practical technique, involves baseline correction of the raw spectra before they are used to derive optical constants. Using the tilt and bend functions provided by the operating system of our spectrometer, baselines for all the spectra were flattened and set to 100% transmittance. The n and k calculation program was then modified to calculate the oscillation expected for the given sample thickness, and this was added to the flattened spectrum prior to calculating the optical constants. Obviously, the major problem with this approach is that the choice of the baseline is somewhat subjective. In practice, however, this was not generally a problem. Many of the experimental spectra were composed of only sharp features (the spectra of CO:CH₄ or CO₂:OCS, for example), which were easily distinguishable from the baseline oscillation. The most challenging ice spectra for this type of treatment were those containing large amounts of H₂O and/or CH₃OH, both of which exhibit broad features of various strengths throughout much of the infrared. In these cases, the point of maximum transmittance between each of the absorption bands was tied to the baseline. The validity of this approach is established (1) by the good agreement between the optical constants we calculate for CH₄, CO, CO₂, and H₂O, and those arrived at by other workers, as noted previously, and (2) by the match between the optical constants derived using this technique and those derived (in a few test cases) using the first technique.

4. INTEGRATED ABSORBANCE VALUES

Integrated absorbance values (A) for many bands in the spectra shown in Figures 2–19 are given in Table 1. These can be used to estimate column densities of ice constituents from the absorption spectra of the ice. Detailed discussions of the quantitative analysis of infrared absorption bands can be found elsewhere (Gribov & Smirnov 1962; Wexler 1967; Pugh & Rao 1970; Person 1981). Since the various definitions of infrared band intensities are considered in detail in these papers, they are not discussed here. Similarly, a detailed discussion of the specific application of the integrated absorbance A to the interpretation of astronomical infrared absorption spectra and the determination of column densities is not presented here, as the topic has been presented elsewhere (cf. d'Hendecourt & Allamandola 1986). The technique used to determine these A values from the absorbance spectra shown in Figures 2–19 will, however, be briefly summarized here.

The A values listed in Table 1 were calculated from

$$A = N^{-1} \int \tau dv , \quad (8)$$

where N is the column density of absorbing molecules (the number of absorbers per unit area) in the beam, $\tau = \ln(I_0/I)$, and the individual integrated band peak areas were determined using a program provided by Nicolet. These values, given in base 10 by the spectrometer, were multiplied by 2.303 to convert them to base e . The largest uncertainty in the derived A values is associated with the uncertainty in the number of absorbers in the sample beam because the densities of most of the ices studied, and the effects of structural changes on these densities as the ices undergo thermal cycling, are not known. We have assumed that the densities of all the ices are 1 g cm^{-3} and that the ices are uniformly thick across the approximately 4 mm diameter focal point of the spectrometer's infrared beam on the sample. We estimate that, for most samples, these assumptions may result in uncertainties no larger than 30%. The column density of the sample is obtained by multiplying the density by the thickness h and the number of molecules per gram of ice. The latter is simply Avogadro's number divided by the molecular weight of the ice. In the case of a component in a mixed molecular ice, the weighted average molecular weight was used, corrected by the concentration of that component. The thicknesses h of each sample are given in §§ 5.1–5.18.

5. SPECIFIC EXPERIMENTS

Far-infrared spectra and calculated optical constants are presented here only for those ices from which we measured significant absorption features in the 675 to 50 cm^{-1} spectral region. These ices include the pure H_2O , pure CH_3OH , $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3 = 100:50:1:1$ (strong interstellar mix), and $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3 = 100:10:1:1$ (weak interstellar mix) samples. To knit the mid- and far-infrared spectra together, the absorption intensities of the features in the far-infrared were scaled by the ratio of the mid-infrared sample thickness to the far-infrared sample thickness deduced from the flow rate (it was not possible to use the laser interference technique with the polyethylene windows). The far-infrared spectrum was then shifted in transmittance to give the best agreement between the two spectra through the overlap region (675 to 400 cm^{-1}). The data through the overlap region were then averaged, and the average values were used to piece the two spectra together. Then, as was the case for the mid-infrared region, the baseline in the far-infrared region of the composite spectrum was flattened by shifting the point of minimum absorbance between the mid- and far-infrared features to zero. Specific details pertinent to the analysis of each ice mixture, beginning with those for which far-infrared data are included, are presented in the following sections.

Because of space considerations, we will not present complete tabular listings of all the optical constants we have derived. Instead, we present optical constants for our ices only for those temperatures at which the spectral properties of the ice change substantially relative to lower temperatures. In addition, we do not list all the points we calculated for each ice spectrum, but instead we have "thinned" the tables to include fewer points in regions where the values of n and k are not changing rapidly. It is hoped that a listing of all the points for all the ices will be made available on electronic media as a part of the Astrophysical Journal Supplement Series in the near future.

5.1. $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3 = 100:10:1:1$ (Weak Interstellar Mix; Fig. 2, Tables 2A–2F)

Spectra spanning the 4000 to 400 cm^{-1} region of the weak interstellar mix were collected at temperatures of 10, 40, 80, 100, 120, and 140 K. Far-infrared spectra covering the 675 to 50 cm^{-1} region were recorded for the 10, 100, and 140 K ices. The ice sample for the mid-infrared spectra was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.56 \mu\text{m}$. The far-infrared sample was deposited at a rate of $6.3 \mu\text{m hr}^{-1}$ to an estimated thickness of $1.1 \mu\text{m}$. Optical constants were calculated at a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) over all the spectra. This was sufficient to resolve all of the spectral features.

In the spectra, the appearance of a shoulder ($\sim 1035 \text{ cm}^{-1}$) on the 1020 cm^{-1} methanol band was observed at 80 K. This was indicative of a change in the ice structure resulting in the appearance of a second distinct site in which the CH_3OH molecules could reside. Continued warm-up resulted in further conversion of the ice to the new structure. By 120 K, the peak was split with the 1035 and 1020 cm^{-1} features now of comparable intensity. By 140 K, the 1035 cm^{-1} feature was dominant, indicating nearly complete conversion of the ice to its new structure. A structural change between 120 and 140 K was also indicated by the appearance of structure in the O–H stretching region ($\sim 3300 \text{ cm}^{-1}$) and the sharp onset of splitting in the far-infrared feature near 220 cm^{-1} . These changes probably reflect the transformation from an amorphous ice to a type II clathrate structure containing CH_3OH and encapsulations of pure methanol excluded from the clathrate during formation (Blake et al. 1991).

5.2. $\text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3 = 100:50:1:1$ (Strong Interstellar Mix; Fig. 3, Tables 3A–3F)

Spectra spanning the 4000 to 400 cm^{-1} region of the strong interstellar mix were collected at temperatures of 10, 40, 80, 100, 120, and 140 K. Far-infrared spectra covering the 675 to 50 cm^{-1} region were recorded for the 10, 100, and 140 K ices. The ice sample for the mid-infrared spectra was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.56 \mu\text{m}$. The far-infrared sample was deposited at a rate of $8.4 \mu\text{m hr}^{-1}$ to a thickness of $1.1 \mu\text{m}$. The resolution of the optical constants calculated for all the spectra was 2 cm^{-1} (one point every 1 cm^{-1}).

Once again, in the spectra of this ice, a shift from the original residence site of the methanol molecules to a second distinct site is observed between 80 and 140 K as reflected in the 1020 cm^{-1} feature. This is also consistent with the formation of a type II $\text{H}_2\text{O}:\text{CH}_3\text{OH}$ clathrate structure, as Blake et al. (1991) observed this clathrate to form whenever CH_3OH was present at concentrations of 7% or greater relative to H_2O . In addition, a gradual blending of the features in the 2800 – 3600 cm^{-1} region (O–H stretch) is observed over the course of the warm-ups. The onset of crystallization was indicated by the sharpening and appearance of structure in several of the spectral features at 140 K.

5.3. CH_3OH (Fig. 4, Tables 4A–4E)

Spectra spanning the 4000 to 400 cm^{-1} region of pure CH_3OH ice were collected at temperatures of 10, 50, 75, 100, and 120 K. Far-infrared spectra covering the 675 to 50 cm^{-1}

region were recorded for the 10, 100, and 120 K ices. The ice sample for the mid-infrared spectra was deposited at a rate of $6.7 \mu\text{m hr}^{-1}$ to a thickness of $0.56 \mu\text{m}$. The far-infrared sample was deposited at the same rate to a estimated thickness of $1.1 \mu\text{m}$. Optical constants were calculated with a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) over the entire spectrum from 4000 to 50 cm^{-1} (the 50 and 75 K spectra were measured only to 400 cm^{-1}). The transformation from amorphous to crystalline methanol between 100 and 120 K was clearly reflected by the dramatic sharpening of bands throughout the spectrum and in the splitting of the O—H stretching feature around 3200 cm^{-1} .

5.4. H₂O (Fig. 5, Tables 5A–5F)

Spectra spanning the 4000 to 400 cm^{-1} region of pure H₂O ice were collected at temperatures of $10, 40, 80, 100, 120$, and 140 K . Far-infrared spectra covering the 675 to 50 cm^{-1} region were recorded for $10, 100$, and 140 K ices. The ice sample for the mid-infrared spectra was deposited at a rate of $2.6 \mu\text{m hr}^{-1}$ to a thickness of $0.41 \mu\text{m}$. The far-infrared sample was deposited at the same rate to a estimated thickness of $1.1 \mu\text{m}$. Optical constants were calculated with a resolution of 4 cm^{-1} (one point every 2 cm^{-1}) between 500 and 50 cm^{-1} . The resolution of the n and k values between 4000 and 500 cm^{-1} is 8 cm^{-1} (one point every 4 cm^{-1}). The gradual change in the spectrum that occurs between 100 and 140 K (a gradual sharpening of the features and the appearance of structure in the “ 3300 ” cm^{-1} O—H stretching band) can be attributed to the transition from amorphous to cubic crystalline ice.

5.5. CH₄ (Fig. 6, Tables 6A–6C)

Spectra spanning the 4000 to 400 cm^{-1} region of pure CH₄ ice were collected for temperatures of $10, 20$, and 30 K . The ice sample was deposited at a rate of $5.4 \mu\text{m hr}^{-1}$ to a thickness of $0.03 \mu\text{m}$. Optical constants were calculated over the 3700 to 1000 cm^{-1} range with a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the CH₄ features (3009 and 1301 cm^{-1}) and 2 cm^{-1} across the rest of the spectrum. This was accomplished by first calculating n and k values across the entire spectrum at a resolution of 2 cm^{-1} . Then, the procedure was repeated at a resolution of 1 cm^{-1} over limited regions surrounding the spectral features (3700 to 2650 cm^{-1} and 1850 to 1100 cm^{-1}). Afterward, the baselines of these 1 cm^{-1} subsets were shifted to match that of the original 2 cm^{-1} data. Finally, these subsets were spliced into the original data to give the final data set. Such a procedure saved a great deal of time in the calculation process.

The 3009 and 1301 cm^{-1} features were split into multiple components at 10 K . At 20 K the substructure coalesced, leaving uniform profiles which broadened with further warm-up.

5.6. CO₂ (Fig. 7, Tables 7A–7D)

Spectra spanning the 4000 to 400 cm^{-1} region of pure CO₂ ice are presented for temperatures of $10, 30, 50$, and 70 K . The ice sample was deposited at a rate of $5.4 \mu\text{m hr}^{-1}$ to a thickness of $0.03 \mu\text{m}$. Optical constants were calculated with a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) across the spectrum.

In the spectrum, both the disappearance of structure in the 2340 cm^{-1} feature and a sharp increase in the splitting of the

660 cm^{-1} feature were observed between 10 and 30 K . The splitting of the 660 cm^{-1} band is due to degeneracy breakdown in the vibrational mode and does not reflect the trapping of CO₂ molecules in two different sites. Between 30 and 70 K only a gradual sharpening of the spectral features was noted.

5.7. OCS (Fig. 8, Tables 8A–8C)

Spectra spanning the 4000 to 400 cm^{-1} region of pure OCS ice are presented for temperatures of $10, 50$, and 60 K . The ice sample was deposited at a rate of $8.4 \mu\text{m hr}^{-1}$ to a thickness of $0.14 \mu\text{m}$. Optical constants over the 3200 to 700 cm^{-1} region were calculated with a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) across the spectrum.

In the spectrum, an abrupt sharpening of the weak features near 860 cm^{-1} (symmetric stretch) and 520 cm^{-1} (O—C—S bend), and a change in the profile of the main 2045 cm^{-1} asymmetric stretching band, reflected a structural change in the ice sample between 50 and 60 K .

5.8. CO:CH₄ = 20:1 (Fig. 9, Tables 9A–9D)

Spectra spanning the 4000 to 400 cm^{-1} region of a CO:CH₄ = 20:1 ice mixture were measured at temperatures of $10, 15, 20$, and 25 K . The ice sample was deposited at a rate of $5.6 \mu\text{m hr}^{-1}$ to a thickness of $0.14 \mu\text{m}$. Optical constants were calculated over the 3500 to 1000 cm^{-1} region at a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the methane features in the spectrum (1500 to 1150 cm^{-1} and 3300 to 2750 cm^{-1}) and 2 cm^{-1} (one point every 1 cm^{-1}) elsewhere. This was accomplished by a procedure identical to that used for the analysis of the pure CH₄ ice data. Only a gradual broadening of the spectral features was observed upon warm-up.

5.9. CO:OCS = 20:1 (Fig. 10, Tables 10A–10D)

Spectra spanning the 4000 to 400 cm^{-1} region of a CO:OCS = 20:1 ice mixture were collected at temperatures of $10, 20, 25$, and 30 K . The ice sample was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.14 \mu\text{m}$. Optical constants were calculated over the 2500 to 1600 cm^{-1} region with a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the spectrum.

In the measured spectra, the OCS asymmetric stretching band at 2048 cm^{-1} split between 20 and 25 K , giving rise to a secondary component at 2043 cm^{-1} . By 30 K the 2043 cm^{-1} component was dominant and the profile indicated further underlying structure. In addition, the FWHM of the peak nearly doubled (from 14 to 26 cm^{-1}) between 20 and 30 K .

5.10. CO₂:CH₄ = 20:1 (Fig. 11, Tables 11A–11E)

Due to the great disparity between the absorption intensities of the CH₄ bands and that of the CO₂ bands, two sets of spectra spanning the 4000 to 400 cm^{-1} region of this ice mixture were collected at temperatures of $10, 20, 30, 50$, and 70 K . First, spectra of a “thick” sample were measured to obtain a reasonable signal-to-noise level through the relatively weak CH₄ features. This sample was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.87 \mu\text{m}$. The CO₂ features in this spectrum were saturated. To facilitate accurate measurements of the CO₂ bands, a second, thinner ice sample was prepared and mea-

sured. This thin sample was deposited at a rate of $4.4 \mu\text{m hr}^{-1}$ to a depth of $0.14 \mu\text{m}$. Optical constants were calculated between 3800 and 500 cm^{-1} with a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the CH_4 features (3009 and 1309 cm^{-1}), and 2 cm^{-1} (one point every 1 cm^{-1}) across the rest of the spectrum. This was accomplished in a similar fashion to the pure CH_4 calculations. First, optical constants were calculated across the entire spectrum of the thin ice at a resolution of 2 cm^{-1} . Then optical constants were calculated at a resolution of 1 cm^{-1} over the CH_4 bands (3300 to 2900 cm^{-1} and 1500 to 1150 cm^{-1}) for the thick ice spectra. These results were then tilted and shifted to match the baseline imposed by the dominant CO_2 features in the thin sample data set, and spliced into those data.

The CH_4 absorption features in the spectra were split, indicating that the methane molecules were in two distinct sites within the ice. This structure remained throughout the warm-ups. The CO_2 features behaved as did those for the pure CO_2 ice.

5.11. $\text{CO}_2:\text{OCS} = 20:1$ (Fig. 12, Tables 12A–12C)

Spectra spanning the 4000 to 400 cm^{-1} region of a $\text{CO}_2:\text{OCS} = 20:1$ ice mixture are presented for temperatures of 10 , 30 , and 70 K . The ice sample was deposited at a rate of $6.3 \mu\text{m hr}^{-1}$ to a thickness of $0.07 \mu\text{m}$. Optical constants were calculated at a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the main features in the spectrum (2600 to 1900 cm^{-1} and 800 to 550 cm^{-1}) and 2 cm^{-1} (one point every 1 cm^{-1}) elsewhere. This was accomplished by a procedure identical to that used for the analysis of the pure CH_4 ice data.

In the spectrum, a shift of 8 cm^{-1} (from 2047 to 2055 cm^{-1}) and the appearance of a shoulder (2042 cm^{-1}) was noted in the OCS asymmetric stretching band between 10 and 30 K . The intensity of this shoulder decreased between 30 and 70 K .

5.12. $\text{H}_2\text{O}:\text{CH}_4 = 20:1$ (Fig. 13, Tables 13A–13F)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{H}_2\text{O}:\text{CH}_4 = 20:1$ ice mixture were measured at temperatures of 10 , 40 , 80 , 100 , 120 , and 140 K . The ice sample was deposited at a rate of $2.8 \mu\text{m hr}^{-1}$ to a thickness of $0.56 \mu\text{m}$. Optical constants were calculated with a resolution of 3 cm^{-1} (one point every 1.5 cm^{-1}) across the spectrum. The structure observed in the band profiles of pure CH_4 at 10 K was not present in this mixture. The H_2O features and their behavior upon warm-up were essentially unchanged from that of pure H_2O ice.

5.13. $\text{H}_2\text{O}:\text{OCS} = 20:1$ (Fig. 14, Tables 14A–14E)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{H}_2\text{O}:\text{OCS} = 2:1$ ice mixture are presented for temperatures of 10 , 40 , 100 , 120 , and 140 K . The ice sample was deposited at a rate of $4.8 \mu\text{m hr}^{-1}$ to a thickness of $0.28 \mu\text{m}$. Optical constants were calculated with a resolution of 3 cm^{-1} (one point every 1.5 cm^{-1}) across the spectrum. Again, the water bands in the spectrum are essentially unaffected by the presence of the OCS. The 2045 cm^{-1} feature of OCS was observed to gradually sharpen over the course of warm-up.

5.14. $\text{H}_2\text{O}:\text{OCS} = 2:1$ (Fig. 15, Tables 15A–15F)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{H}_2\text{O}:\text{OCS} = 2:1$ ice mixture were measured at temperatures of 10 , 40 , 80 , 100 , 120 , and 140 K . The ice sample was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.28 \mu\text{m}$. Optical constants were calculated with a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) across the spectrum. The high concentration of OCS in the ice mixture is sufficient to break up the hydrogen-bonded H_2O lattice, resulting in a relatively strong absorption feature from free O–H bonds at 3645 cm^{-1} . A rearrangement in the structure of the ice mixture between 80 and 100 K is indicated by a sharp reduction in the intensity of this band with respect to the hydrogen-bonded O–H stretching band near 3300 cm^{-1} , and the abrupt sharpening observed in the 2050 cm^{-1} OCS band.

5.15. $\text{N}_2:\text{CH}_4 = 20:1$ (Fig. 16, Tables 16A and 16B)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{N}_2:\text{CH}_4 = 20:1$ ice mixture were measured at temperatures of 10 and 20 K . The ice sample was deposited at a rate of $5.7 \mu\text{m hr}^{-1}$ to a thickness of $1.96 \mu\text{m}$. Optical constants were calculated over the 3400 to 1000 cm^{-1} region at a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the methane features in the spectrum (3400 to 2700 cm^{-1} and 1600 to 1100 cm^{-1}) and 2 cm^{-1} (one point every 1 cm^{-1}) elsewhere. As was the case with the other mixtures involving CH_4 , this was accomplished by a procedure identical to that used for the analysis of the pure CH_4 ice data. No structure was evident in the spectral bands at either temperature, and only a modest broadening of these features was observed with warm-up. The N_2 stretching fundamental was perturbed into activity in this ice. It falls at 2328 cm^{-1} ($\text{FWHM} = \sim 2 \text{ cm}^{-1}$, $A = 7 \times 10^{-22} \text{ cm molecule}^{-1}$) with an intensity $1/750$ times that of the 1306 cm^{-1} methane band.

5.16. $\text{N}_2:\text{OCS} = 20:1$ (Fig. 17, Tables 17A–17D)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{N}_2:\text{OCS} = 20:1$ ice mixture were measured at temperatures of 10 , 15 , 20 , and 25 K . The ice sample was deposited at a rate of $4.2 \mu\text{m hr}^{-1}$ to a thickness of $0.28 \mu\text{m}$. Optical constants were calculated over the 3000 to 700 cm^{-1} region with a resolution of 2 cm^{-1} (one point every 1 cm^{-1}) across the spectrum.

A general broadening in the OCS asymmetric stretching feature near 2050 cm^{-1} was observed between 10 and 20 K . A marked broadening and change in shape was observed in the profile of this band between 20 and 25 K . The N_2 stretching fundamental could not be observed in this experiment.

5.17. $\text{O}_2:\text{CH}_4 = 20:1$ (Fig. 18, Tables 18A–18C)

Spectra spanning the 4000 to 400 cm^{-1} region of an $\text{O}_2:\text{CH}_4 = 20:1$ ice mixture were measured at temperatures of 10 , 20 , and 30 K . The ice sample was deposited at a rate of $4.5 \mu\text{m hr}^{-1}$ to a thickness of $2.98 \mu\text{m}$. Optical constants were calculated over the 3400 to 1000 cm^{-1} region at a resolution of 1 cm^{-1} (one point every 0.5 cm^{-1}) across the methane features in the spectrum (3300 to 2700 cm^{-1} and 1600 to 1100 cm^{-1}) and 2 cm^{-1} (one point every 1 cm^{-1}) elsewhere. This was ac-

complished by a procedure identical to that used for the analysis of the pure CH₄ ice data.

In the spectrum, the C—H stretching feature at 10 K was observed at 3030 cm⁻¹ with a shoulder near 3014 cm⁻¹. Between 20 and 30 K much of the intensity in this region shifted to the 3014 cm⁻¹ position. The C—H bending feature near 1306 cm⁻¹ was observed to shift slightly (~ 2 cm⁻¹) to lower frequency and broaden in this temperature increment. In addition, the O₂ stretching fundamental was perturbed into activity in this ice mixture. It was observed at 1548 cm⁻¹ (FWHM ≈ 6 cm⁻¹, $A \approx 5 \times 10^{-21}$ cm molecule⁻¹) with an intensity $\sim 1/70$ times that of the 1306 cm⁻¹ methane band.

5.18. O₂:OCS = 20:1 (Fig. 19, Tables 19A and 19B)

Spectra spanning the 4000 to 400 cm⁻¹ region of an O₂:OCS = 20:1 ice mixture were measured at temperatures of 10 and 20 K. The ice sample was deposited at a rate of 4.9 $\mu\text{m hr}^{-1}$ to a thickness of 0.45 μm . Optical constants were calculated over the 3000 to 700 cm⁻¹ region with a resolution of 2 cm⁻¹ (one point every 1 cm⁻¹) across the spectrum. Only a slight broadening of the spectral features was observed in the warm-up. Once again, the O₂ stretching fundamental was ob-

served to be weakly active lying at 1548 cm⁻¹ (FWHM = ~ 6 cm⁻¹, $A \approx 3 \times 10^{-20}$ cm molecule⁻¹) with an intensity about one-fifth that of the 860 cm⁻¹ OCS feature.

5.19. Pure CO (Fig. 20, Table 20)

We have previously obtained infrared spectra of pure CO (Sandford et al. 1988) from which optical constants were derived and used to interpret astronomical spectra (Tielens et al. 1991). Since these optical constants do not appear in tabular form in either of the two previous references, they are presented here for completeness. Spectra spanning the 4000 to 400 cm⁻¹ region of pure CO ice were collected at a temperature of 10 K. The ice sample was deposited at a rate of 2.6 $\mu\text{m hr}^{-1}$ to a thickness of 0.025 μm . Optical constants were calculated with a resolution of 1 cm⁻¹ (one point every 0.5 cm⁻¹) between 2100 and 2185 cm⁻¹.

This work was partially supported by NASA grants 399-50-00-05 and 199-52-12-04. D. M. H. wishes to acknowledge the support of the National Research Council in the form of an associateship.

FIG. 3.—The 4000 to 50 cm⁻¹ transmission spectra and optical constants (n and k) of a H₂O:CH₃OH:CO:NH₃ = 100:50:1:1 ice mixture at temperatures of 10, 40, 80, 100, 120, and 140 K. The original ice was deposited at 10 K.

FIG. 4.—The 4000 to 50 cm^{-1} transmission spectra and optical constants (n and k) of a pure CH_3OH ice at temperatures of 10 , 50 , 75 , 100 , and 120 K . The original ice was deposited at 10 K .

FIG. 5.—The 4000 to 50 cm^{-1} transmission spectra and optical constants (n and k) of a pure H_2O ice at temperatures of 10 , 40 , 80 , 100 , 120 , and 140 K . The original ice was deposited at 10 K .

FIG. 6.—The 3100 to 2950 cm⁻¹ and 1400 to 1200 cm⁻¹ transmission spectra and optical constants (*n* and *k*) of a pure CH₄ ice at temperatures of 10, 20, and 30 K. The original ice was deposited at 10 K.

FIG. 7.—The 4000 to 500 cm⁻¹ transmission spectra and optical constants (n and k) of a pure CO₂ ice at temperatures of 10, 30, 50, and 70 K. The original ice was deposited at 10 K.

FIG. 9.—The 3500 to 1000 cm^{-1} transmission spectrum and optical constants (n and k) of a $\text{CO:CH}_4 = 20:1$ ice mixture at 10 K . The insets show expansions of the CH_4 features in the 3100 to 2950 cm^{-1} and 1400 to 1200 cm^{-1} regions for the ice at temperatures of 10 , 15 , 20 , and 25 K . The original ice was deposited at 10 K .

FIG. 11.—The 4000 to 500 cm^{-1} transmission spectrum and optical constants (n and k) of a $\text{CO}_2:\text{CH}_4 = 20:1$ ice mixture at 10 K . The insets show expansions of the CH_4 features in the 3100 to 2950 cm^{-1} and 1400 to 1200 cm^{-1} regions for the ice at temperatures of $10, 20, 30, 50$, and 70 K . The original ice was deposited at 10 K .

FIG. 13.—The 4000 to 500 cm^{-1} transmission spectrum and optical constants (n and k) of a $\text{H}_2\text{O}:\text{CH}_4 = 20:1$ ice mixture at 10 K. The insets show expansions of the CH_4 features in the 3050 to 2950 cm^{-1} and 1400 to 1200 cm^{-1} regions for the ice at temperatures of 10, 40, 80, 100, 120, and 140 K. The original ice was deposited at 10 K.

FIG. 14.—The 4000 to 500 cm⁻¹ transmission spectra and optical constants (n and k) of an H₂O:OCS = 20:1 ice mixture at temperatures of 10, 40, 100, 120, and 140 K. The original ice was deposited at 10 K.

FIG. 17.—The 3000 to 600 cm^{-1} transmission spectra and optical constants (n and k) of an N_2 :OCS = 20:1 ice mixture at temperatures of 10, 15, 20, and 25 K. The original ice was deposited at 10 K.

FIG. 18.—The 3100 to 2950 cm^{-1} and 1400 to 1200 cm^{-1} transmission spectra and optical constants (n and k) of an $\text{O}_2:\text{CH}_4 = 20:1$ ice mixture at temperatures of 10, 20, and 30 K. The original ice was deposited at 10 K.
